THE SUNYAEV-ZEL'DOVICH EFFECT IN A SAMPLE OF 31 CLUSTERS: A COMPARISON BETWEEN THE X-RAY PREDICTED AND *WMAP* OBSERVED COSMIC MICROWAVE BACKGROUND TEMPERATURE DECREMENT

Richard Lieu,[1] Jonathan P. D. Mittaz,[1] and Shuang-Nan Zhang[1,2,3,4]

ABSTRACT

The *WMAP* Q-, V-, and W-band radial profiles of temperature deviation of the cosmic microwave background (CMB) were constructed for a sample of 31 randomly selected nearby clusters of galaxies in directions of Galactic latitude $|b| > 30°$. The profiles were compared in detail with the expected CMB Sunyaev-Zel'dovich effect (SZE) caused by these clusters, with the hot gas properties of each cluster inferred observationally by applying gas temperatures as measured by *ASCA* to isothermal β-models of the *ROSAT* X-ray surface brightness profiles, with the *WMAP* point-spread function fully taken into consideration. After co-adding the 31 cluster fields to significantly reduce the systematic and random uncertainties, it appears that *WMAP* detected the SZE in all three bands. Quantitatively, however, the observed SZE only accounts for about 1/4 of the expected decrement. The discrepancy represents too much unexplained extra flux: in the W band, the detected SZE corresponds on average to 5.6 times less X-ray gas mass within a $10'$ radius than the mass value given by the *ROSAT* β-model. We critically examined how the X-ray prediction of the SZE may depend on our uncertainties in the density and temperature of the hot intracluster plasma, and emission by cluster radio sources. Although our comparison between the detected and expected SZE levels is subject to a margin of error, the fact remains that the average observed SZE depth and profile are consistent with those of the primary CMB anisotropy, i.e., the overall *WMAP* temperature decrement among the 31 rich clusters is too shallow to necessitate an interpretation in terms of an additional effect like the SZE. A unique aspect of this SZE investigation is that because all the data being analyzed are in the public domain, our work is readily open to scrutiny by others.

Subject heading: galaxies: clusters: general

1. INTRODUCTION

One vital test of the present cosmological paradigm is the search for scattering of the CMB by foreground structures such as clusters of galaxies. Such observations can provide important information both about clusters of galaxies as well as basic cosmological parameters like H_0. For the CMB, scattering arises from the Compton interaction with free electrons in the hot (X-ray temperature) plasma of clusters of galaxies, which removes Rayleigh-Jeans blackbody flux in the direction of a cluster, and leads to an apparent decrease in the CMB temperature, a phenomenon known as the Sunyaev-Zel'dovich effect (SZE). By now, the degree of SZE is highly predictable for many clusters of galaxies, because their hot intracluster medium (ICM) properties are well-measured by X-ray satellite missions.

In this work we propose to perform just such a detailed comparison. Of course, in the earlier papers that involved satellite data (see § 6 on interferometric techniques), the X-ray morphology and spectra of many clusters have already been investigated in depth, while marginal detections of the SZE by *WMAP* (*Wilkinson Microwave Anisotropy Probe*) were reported for individual and entire ensembles of clusters (Bennett et al. 2003a; Myers et al. 2004; Hernandez-Monteagudo et al. 2004a, et al. 2004b; Afshordi et al. 2005). Nonetheless, our work in this paper represents the first time the SZE *in radial profiles of fluxes with errors*, rather than in false color significance maps, is shown in

three separate passbands for individual clusters within a large (31 member) sample, leading to an in-depth evaluation of whether the *WMAP* SZE profiles are consistent with the hot-ICM profiles and temperatures, as measured by X-ray missions.

2. THE CLUSTER SAMPLE AND PREDICTED SZE PROFILES FROM X-RAY DATA

The sample employed for our purpose is the Bonamente et al. (2002) catalog of 38 nearby clusters of galaxies (hereafter simply referred to as the Bonamente sample) located in directions of high Galactic latitude ($|b| > 30°$) and low column density of Galactic neutral hydrogen. The rationale has to do with our original intention of using the SZE as a sensitive probe of any extra baryonic matter that may exist in the outskirts of clusters in the form of a warm gas. Since this aim led eventually to a different and much more surprising finding, we will no longer discuss it, except to mention that there is no reason why the members of the Bonamente list should constitute a biased sample in any way, as far as their utility as a probe of the CMB distance scale is concerned. To the contrary, their high $|b|$ location means that the *WMAP* data for these clusters have minimal Galactic foreground-contamination problems.

In order to assess whether the temperature feature recorded by *WMAP* at the position of these clusters is consistent with SZE from the X-ray–emitting hot ICM, it is necessary to first determine the radial distribution of the hot ICM density of each cluster, using the data of X-ray observatories. In particular, we employed the *ROSAT* (*Röntgensatellit*) database, because the *ROSAT* XRT has a sufficiently large field of view to enable background determination even for the very extended nearby clusters in the sample, such as Coma. For clusters without a "cooling flow," the standard isothermal β model is fitted to the X-ray surface brightness $I_X(\theta)$ in the entire region from the X-ray centroid $\theta = 0$ to

Fɪɢ. 1.—Isothermal β-model (eq. [1]) fits to the *ROSAT* X-ray surface-brightness data of the Bonamente et al. (2002) sample of clusters. The *ROSAT* mission was chosen because of its wide field of view, which allows one to determine clearly the surrounding background level even for the larger clusters. For non-isothermal "cooling flow" clusters, the central region where the phenomenon occurs is excluded from our analysis.

the background. Specifically, three parameters are fixed by modeling the surface brightness profile:

$$I_X(\theta) \propto n_0^2 \left[1 + (\theta/\theta_c)^2 \right]^{-3\beta+(1/2)}, \qquad (1)$$

where θ_c is the core radius, n_0 is the central electron number density, and β is the decay index. To predict the SZE, another cluster parameter, the temperature T of the clusters, is also needed; these were taken from Bonamente et al. (2002). Where possible,

the temperatures were measured by *ROSAT*, although *ASCA* (*Advanced Satellite for Cosmology and Astrophysics*) data were used when a cluster's ICM is too hot for *ROSAT*'s passband. With the advent of *XMM-Newton* and *Chandra*, the reported temperatures corroborate *ASCA*, but are generally slightly higher than the *ROSAT* values. Since the SZE depth enhances with increasing *T*, the Bonamente temperatures are in fact too conservative for estimating this depth.

For "cooling flow" clusters, the central region where cooling occurs is excluded from the modeling. The repercussions of such

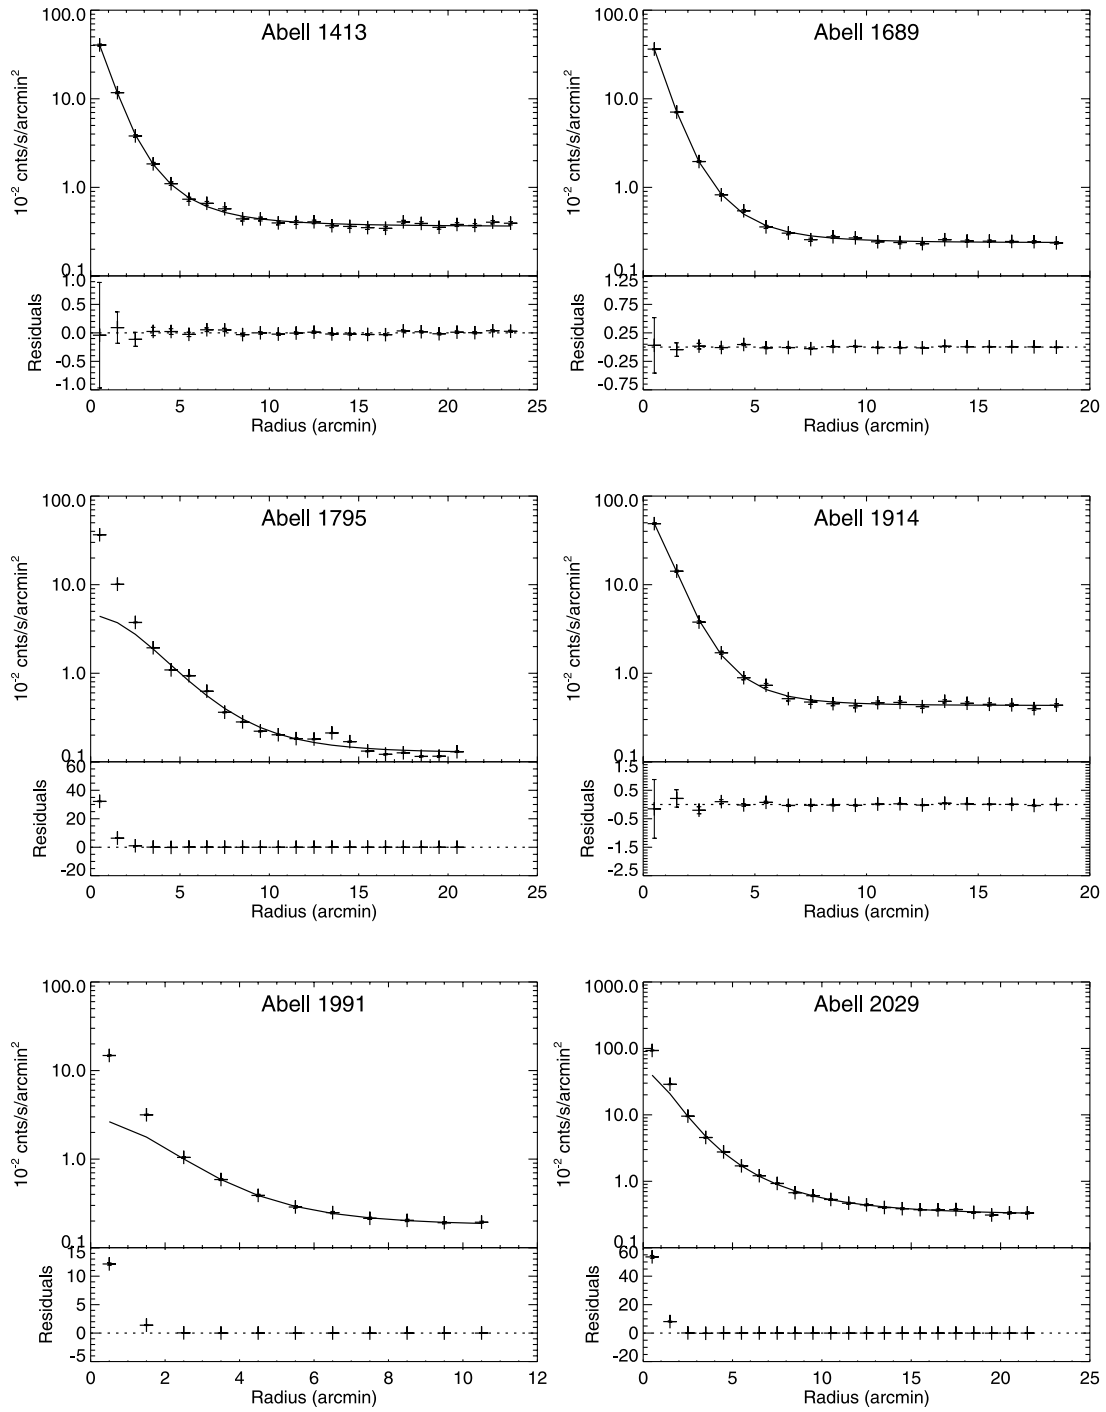

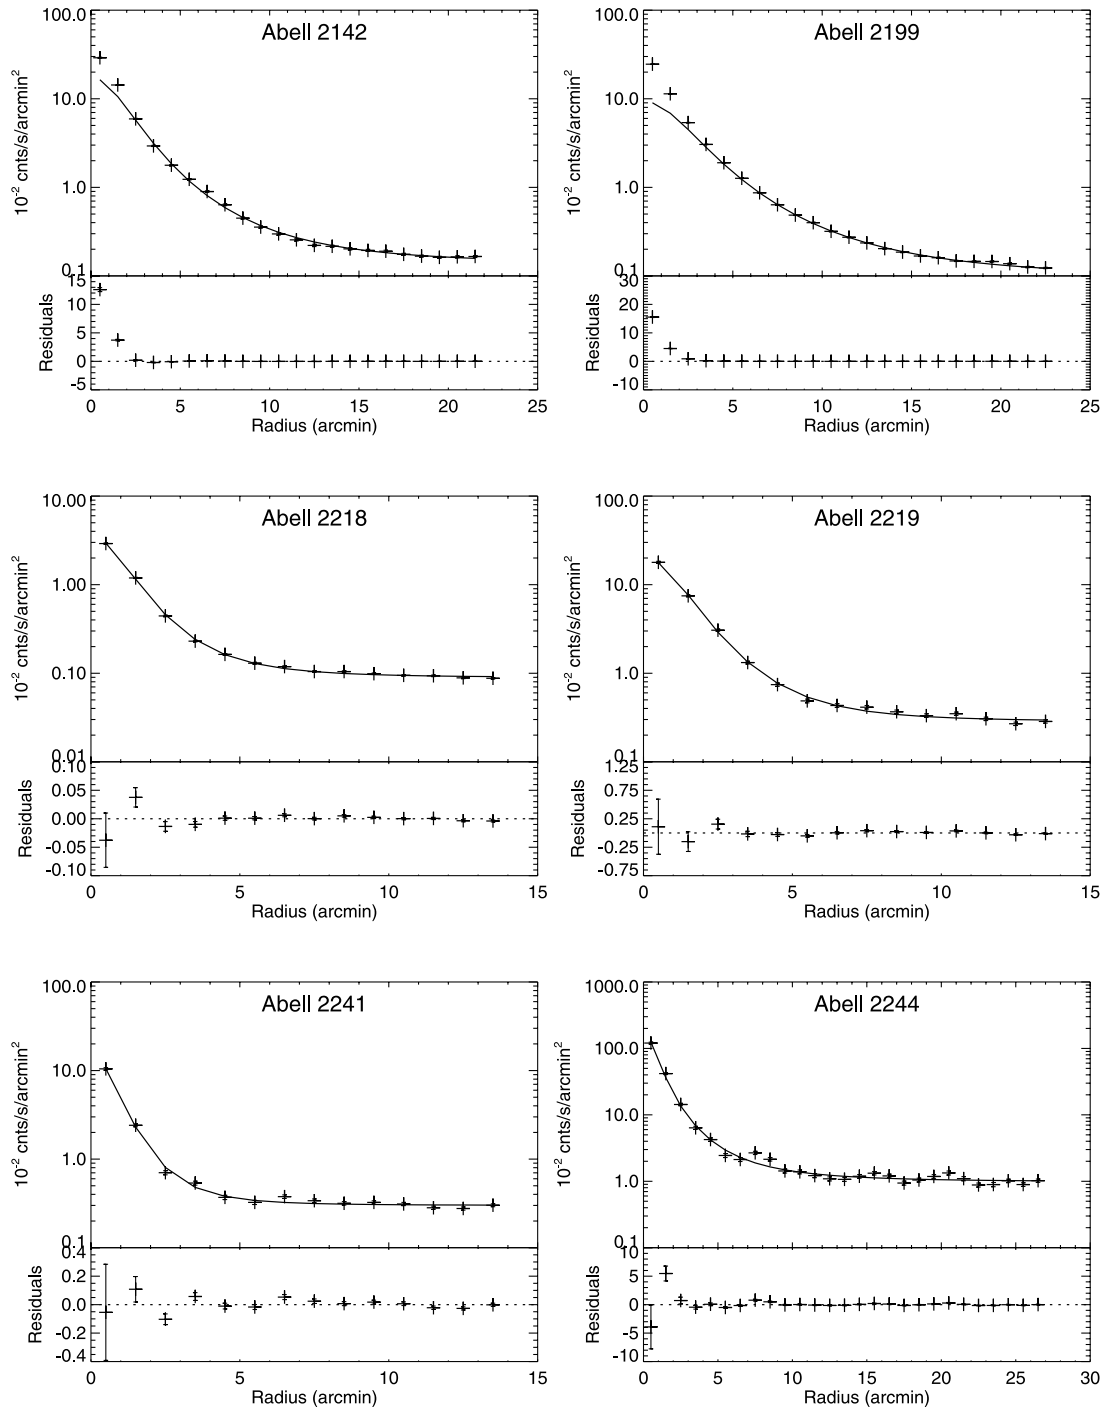

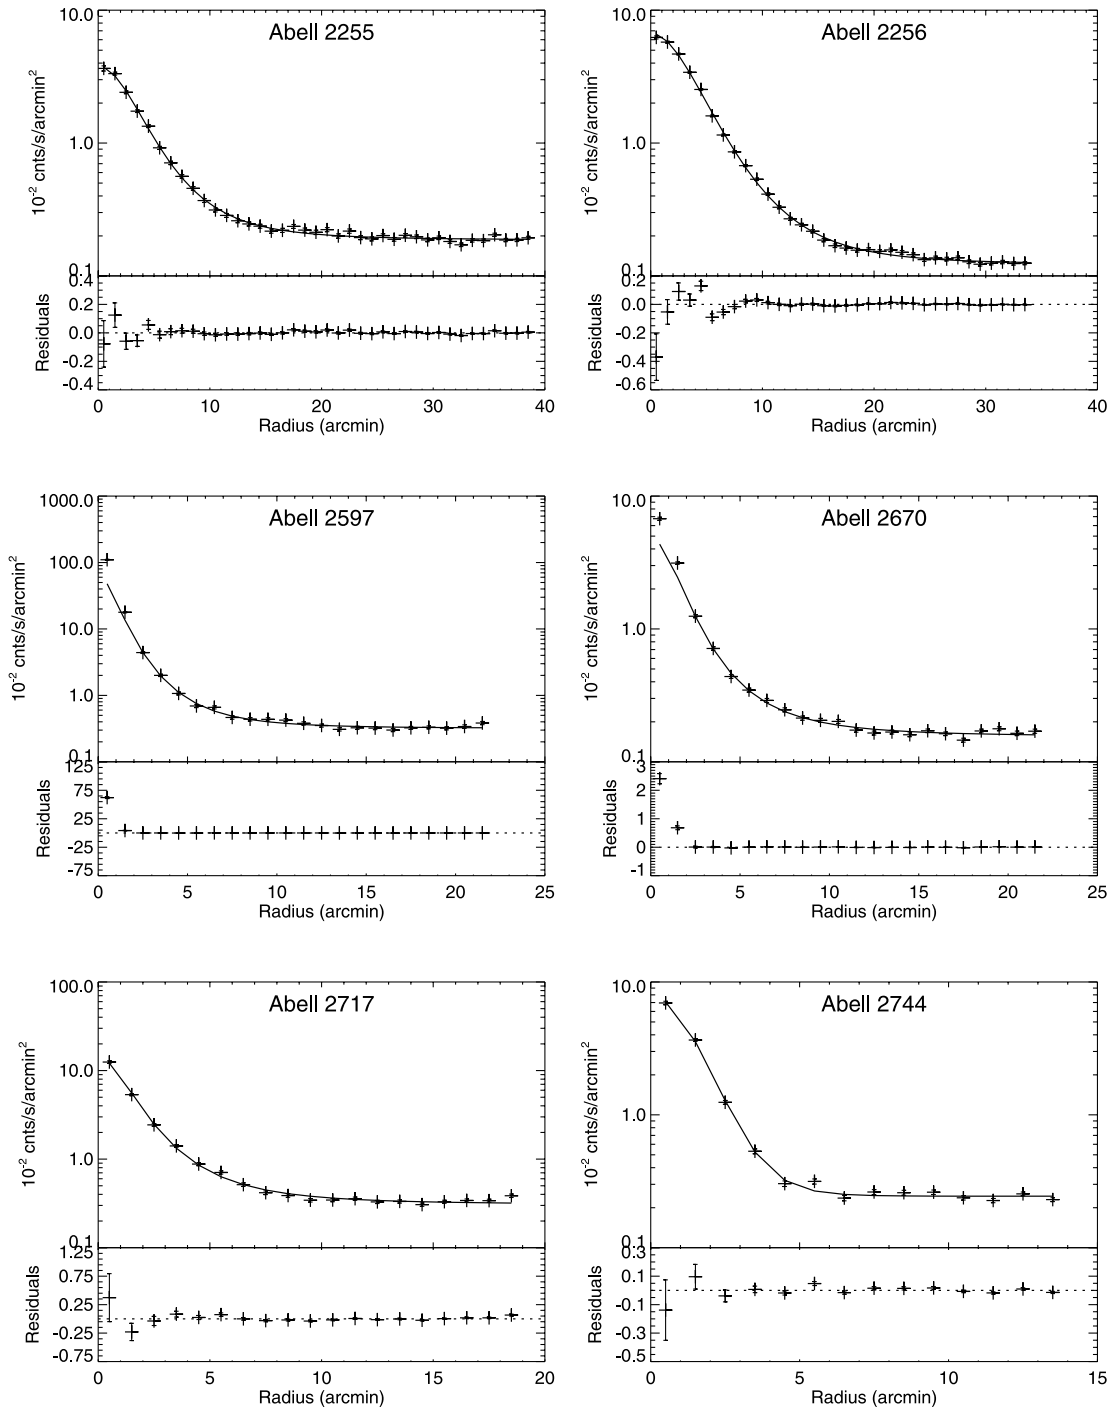

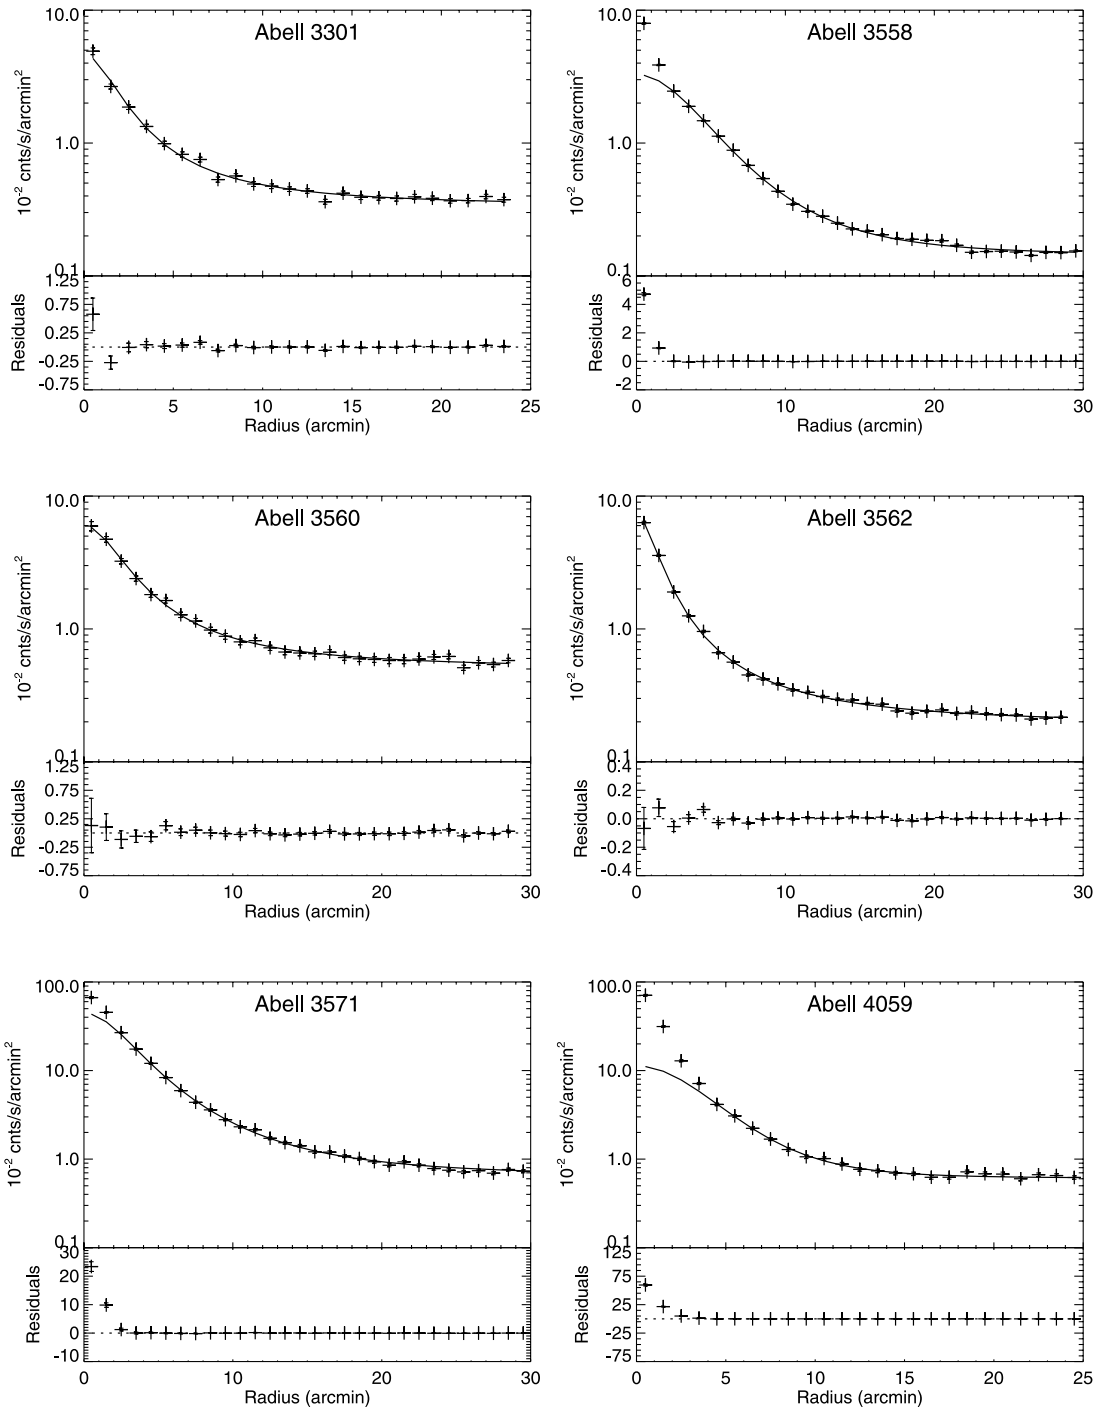

FIG. 1.—*Continued*

a procedure are discussed at length in § 5, where high-resolution *XMM-Newton* data are used to demonstrate that any errors in the SZE associated with this analysis method are too small to affect our final conclusions. All the *ROSAT* radial profiles of the member clusters of the Bonamente sample are shown in Figure 1. The best-fit β-model parameters, together with other essential details of each cluster, are found in Table 1, where a spot check against Briel & Henry (1996) reveals reasonable agreement with their values of $n_0 = (3.15 \pm 0.29) \times 10^{-3}$ cm^{-3}, $\theta_c = 5'.15 \pm 0'.46$, and $\beta = 0.93 \pm 0.04$ for A1795.

Note.—The β-model parameters are derived from *ROSAT* observations. X-ray properties of the 31 clusters employed for the present SZE investigation. The β-model parameters are derived from *ROSAT* observations.
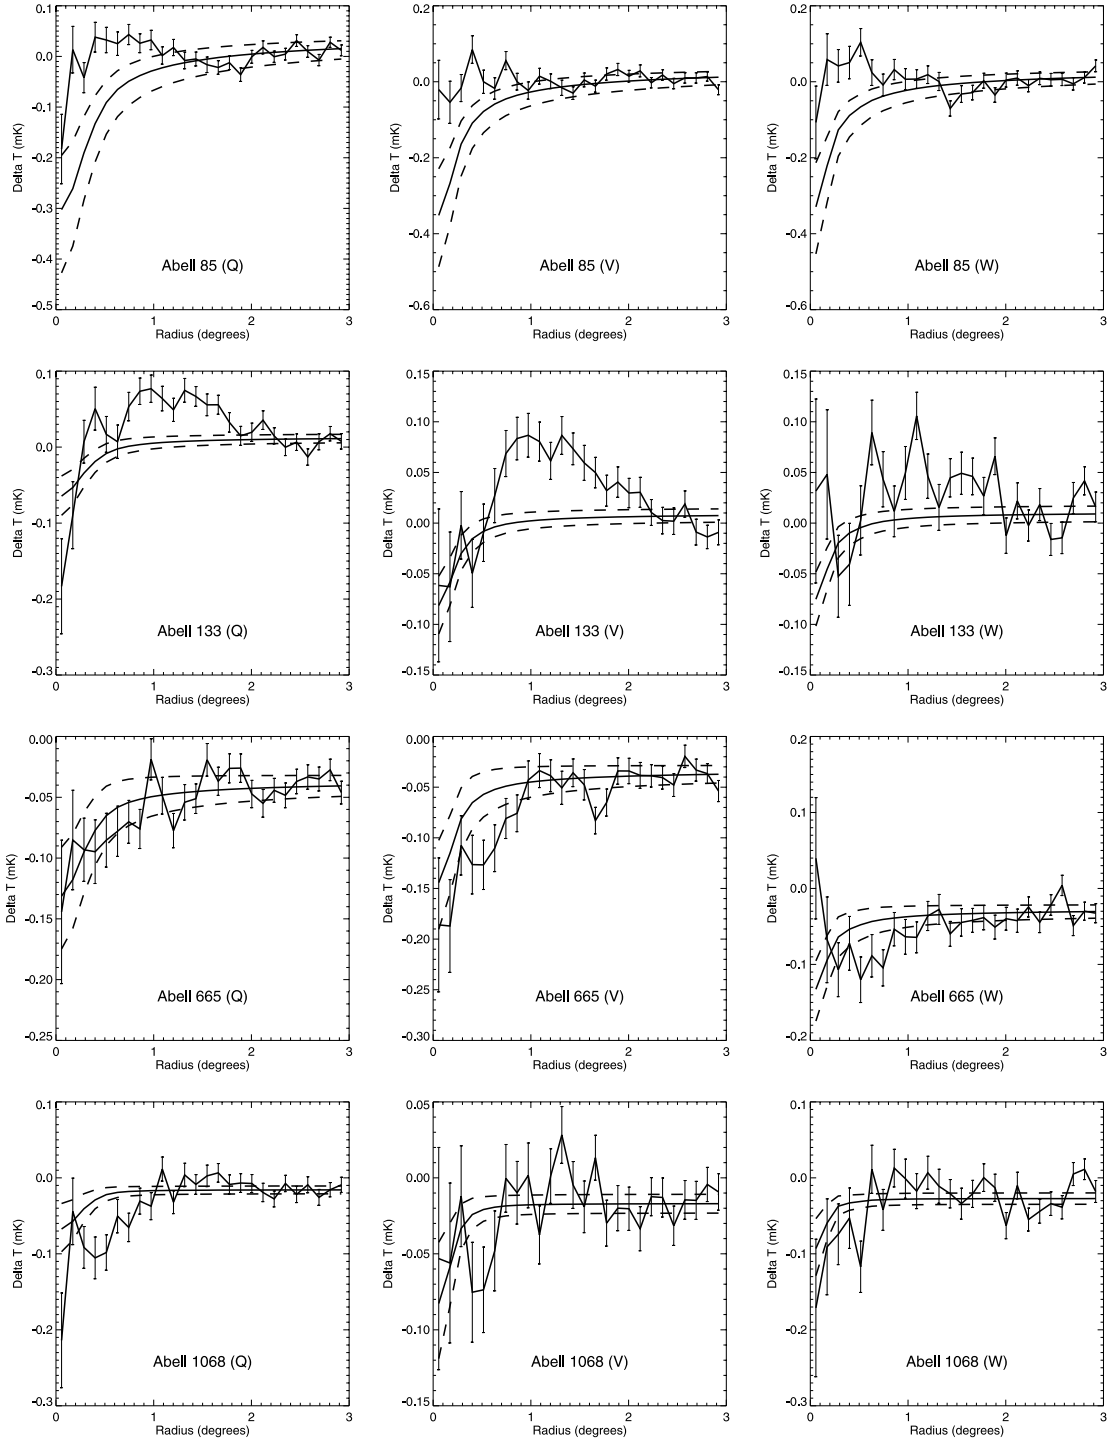

FIG. 2.—*WMAP* Q, V, and W band radial profiles of the CMB temperature deviation (from the all-sky mean value) as averaged over concentric annuli centered at the positions of the 31 clusters employed in our analysis. The data were plotted after subtraction of the contribution from the CMB dipole and quadrupole anisotropy. The solid line gives the SZE temperature decrement profile expected from the hot ICM, with properties determined by X-ray observations (including the *ROSAT* β model of Fig. 1) and displayed in Table 1. Dashed lines mark the 90% error margin on the prediction, based on uncertainties in the observed hot ICM parameters. The continuum level for the predicted SZE profile is fixed by aligning it with the average temperature deviation in the outermost ($2°–3°$) annuli. This is a reliable procedure because, according to the analysis of random fields, the large annuli averages stabilize to values near zero (see Fig. 8).

Fig. 2.—Continued
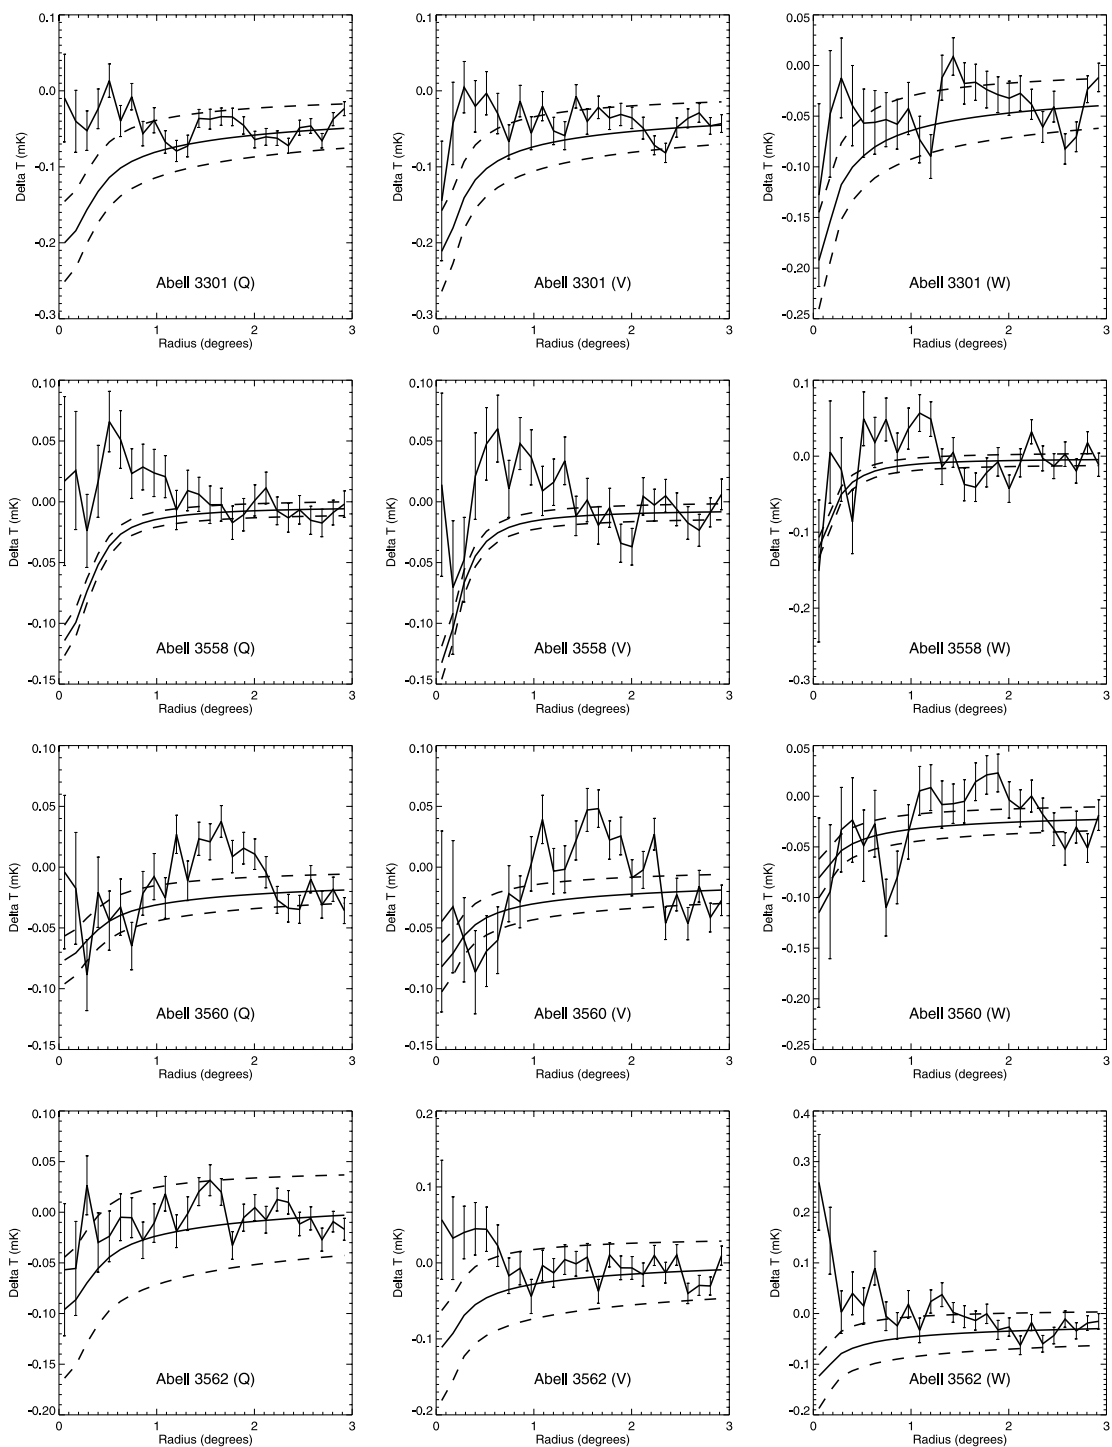

Fig. 2.—*Continued*

Fig. 2.—*Continued*

FIG. 2.—*Continued*

Fig. 2.—*Continued*

The predicted SZE decrement as a function of angle relative to the cluster center direction is then given by

$$\frac{\Delta T_{SZ}(\theta)}{T_{CMB}} = \frac{kT}{m_e c^2} \sigma_{Th} \int dl \, n_e \left[\frac{x(e^x + 1)}{e^x - 1} - 4 \right], \qquad (2)$$

where $x = h\nu/kT_{CMB}$, where ν is the mean frequency of the *WMAP* observing filter, σ_{Th} is the Thomson cross section, l is the path length through the cluster along our off-axis sight line, and the electron density is

$$n_e(r) = n_0 \left[1 + (r/r_c)^2 \right]^{-3\beta/2}, \qquad (3)$$

with $r = r(l, \theta)$ being the radius. The integration of equation (2) was performed analytically by previous authors, resulting in an expression for $\Delta T_{SZ}(\theta)/T_{CMB}$, which depends on n_0, β, and the core radius $r_c = L\theta_c$, where $L = cz/H_0$ (with $H_0 = 71$ km s^{-1} Mpc^{-1}) is the distance to a nearby cluster (see, e.g., Refregier et al. 2000). We do not repeat these earlier calculations, except to say that on application of our Coma Cluster β-model parameters to the analytical formula, we obtained $\Delta T_{SZ}(\theta = 0)/T_{CMB} \approx -590 \pm 170$ μK at the *WMAP* frequency of $\nu = 41$ GHz. This compares well with the estimate by other groups, such as the

value of $\Delta T_{SZ}(\theta = 0)/T_{CMB} \approx -507 \pm 92.7$ μK at 32 GHz, as obtained by Herbig et al. (1995).

3. THE CLUSTER *WMAP* TEMPERATURE PROFILES; EFFECT OF THE POINT-SPREAD FUNCTION

To examine whether the *WMAP* mission detected temperature variation in the fields of the Bonamente sample, we extracted "thumbnail" images (small maps) from the *WMAP* first-year database centered at the X-ray centroids of the 38 clusters, i.e., the coordinates as listed in Table 1. Clusters with bright radio sources along their sight lines (Virgo, A21, A1045) are excluded from further analysis. In addition, Fornax, A1314, and A1361 were excluded because of difficulties in estimating the uncertainty in the X-ray brightness distribution. Lastly, Hercules was not considered because the exact location of the cluster emission could not be identified unambiguously. For the remaining 31 sample members, radial profiles of the mean temperature deviation over concentric annuli are computed after removing the dipole and quadrupole components, plotted in Figure 2, where the error bars for each radius interval reflect an antenna noise that scales as the inverse square root of the number of observations of the sky area. We restrict attention to the cosmological bands of Q, V, and W, since the K and Ka bands are dominated by Galactic

Fig. 4.—PSF for the *WMAP* W band (as derived from Fig. 3), convolved with the hot ICM model $\beta = 0.74$, $\theta_c = 1'.5$, and amplitude $\Delta T = -0.083$ K. The model parameters are chosen for direct comparison with Fig. 1c of Myers et al. (2004), which displays the temperature profile after the same model was convolved with their estimate of the W-band PSF. It can be seen that the two curves resemble each other very closely. This checks the correctness of our convolution routine.

profiles because they all compare well with each other statistically, even though the sources are located in very different parts of the sky, with the highest being at Galactic latitude $|b| \approx 74°$. This indicates that the performance of *WMAP* in spatially resolving CMB temperature variations is consistent across the sky. The SZE profile of each cluster, as inferred from equation (2) and Table 1, is convolved with the PSF of the appropriate filter. A test of the correctness of our procedure was done by adopting the β model in Figure 1c of Myers et al. (2004). After convolving this model with the W-band PSF, our results are plotted in Figure 4. It bears close resemblance to the corresponding profile in the Myers paper.

With the assurance of the aforementioned cross-checks, the expected SZE decrement for each cluster is seen overplotted in Figure 2, where the unperturbed "continuum" is aligned with the average temperature deviation in the outermost ($2°$–$3°$) annulus. The *co-added* model and data profiles for each filter are shown in Figure 5. In all plots, the error bars for each radius interval reflect an antenna noise that scales as the inverse square root of the number of observations of the sky area. An analysis of the (radial) bin-to-bin variation of the profile of many co-added *random* fields reveals that the degree of relative fluctuation between neighboring radial bins is in accordance with the size of the error bars, as shown in Figure 5, for each bin. This enables us to evaluate the formal statistical significance of the overall detection of a broad temperature decrement feature in the composite radial profiles, as 9, 4.2, and 2.3 σ for the Q, V, and W bands, respectively (see Fig. 5 for more details). Note that the true significances are likely to be less than those given by the three numbers, because systematic effects in the *WMAP* data were not included when we calculated them. Such effects are discussed at length in the next section.

4. SYSTEMATIC CMB TEMPERATURE VARIATION FROM *WMAP* RANDOM FIELDS

From the graphs in Figure 2, a broad CMB temperature decrement positionally coincident with the cluster and of commensurate spatial extent as the cluster size is apparent for some clusters, such as Coma, A1795, A1413, A2199, A2219, and A2255.

Fig. 3.—Gaussian fits to the average profile of 15 point sources, to determine the *WMAP* point-spread function for the Q, V, and W bands. The best-fit model yielded $\sigma = 0°.220$ for Q, $0°.150$ for V, and $0°.115$ for W. The values are in good agreement with those of Myers et al. (2004).

foreground emissions and absorptions (Bennett et al. 2003a, 2003b).

In order to compare any spatial features seen at a cluster position with the expected SZE behavior, it is necessary to take into account the *WMAP* point-spread function (PSF). For each of the three filters, we computed the average brightness profile from 15 point sources and fitted it with a Gaussian function, as shown in Figure 3. It was possible to perform the averaging of these
Fig. 5.—Average *WMAP* observed and predicted radial profile for the 31 clusters of our sample. An individual error bar for each bin depicts the random uncertainty (i.e., *WMAP* antenna noise), while the systematic 1 σ error plotted on the side of the graph depicts the residual large-scale correlated variation in the central 1° region of the 33 co-added random fields of Fig. 8. The continuum of the prediction curve is fixed by alignment with the 2°–3° data. This alignment procedure is justified by Fig. 8, where it was shown that when 33 random fields were co-added, the 2°–3° annulus exhibits high stability.

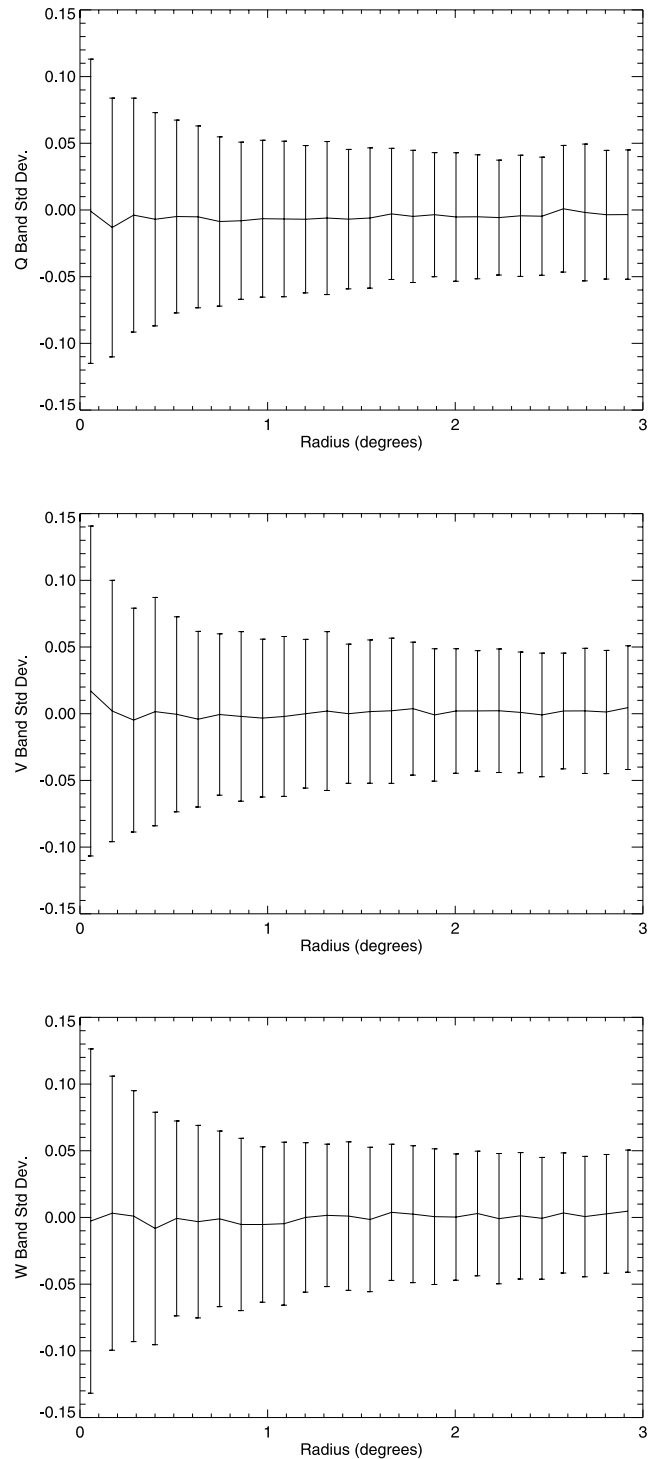

Fig. 6.—The rms field-to-field variation of CMB temperature at a given radial interval, and for the Q, V, and W bands of *WMAP*, as obtained by comparing the radial profile of 100 random pointings.

On the other hand, there are clearly counter examples like A85, A1367, A1689, A2029, A3301, A3558, and A3571. There are also clusters that fall within a "gray" zone, where no judgment can be made at all. Apart from some clusters having small expected SZE amid poor signal-to-noise ratio, another key problem that weakens any verdict from an individual cluster is the ambiguity in the CMB temperature "continuum" appropriate to the observation. In fact, we are dealing with a nontrivial systematic uncertainty that can only be understood by examining many
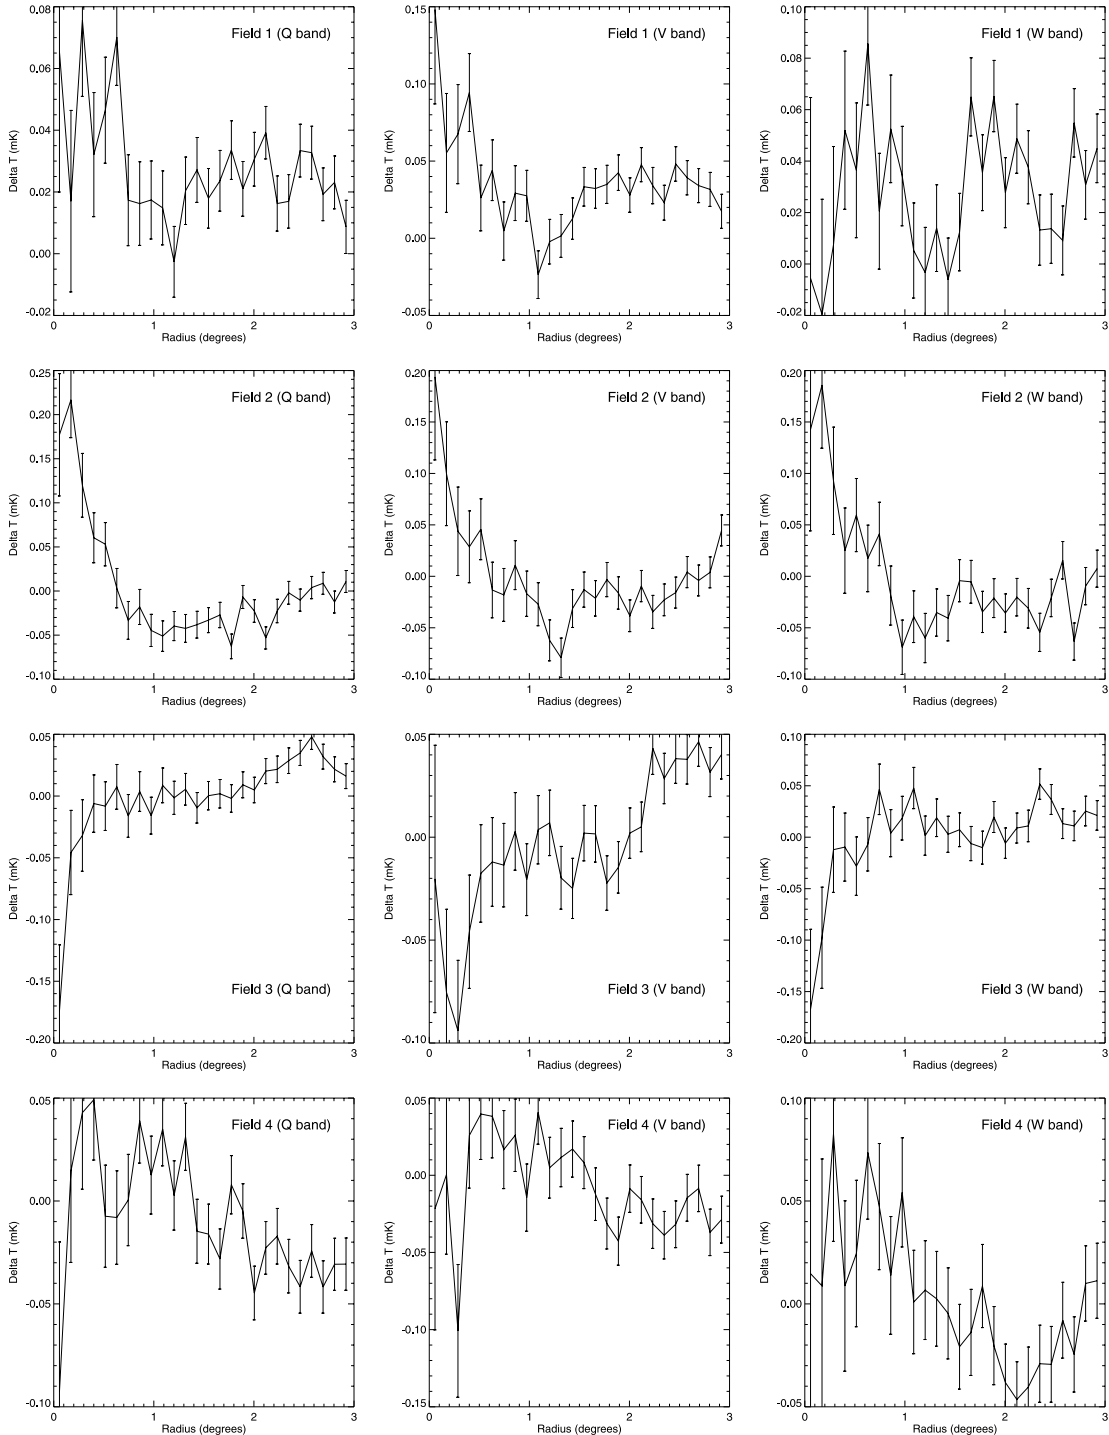

Fɪɢ. 7.—*WMAP* Q, V, and W band radial profile (of CMB temperature deviation) centered at four randomly chosen positions on the sky.

randomly chosen fields across the *WMAP* sky with $|b| \geq 30°$. For this reason, we constructed radial profiles for 100 such fields.

A plot of the rms. variation (from one random field to another) of the temperature difference at each radial interval is shown in Figure 6, where it is evident that systematic effects at the level of 0.1 mK are commonplace among the smaller radius annuli. To be even more specific, we display in Figure 7 the radial profiles of four random fields. It can be seen that degree-scale modulations are frequently present, with an amplitude of ≈0.1 mK, often found at the $\theta = 0$ (i.e., on-axis) position. The phenomenon

pertains to the most prominent fluctuation in the *WMAP* data (the primary acoustic peak), which has an amplitude of $\Delta T_{CMB} \approx$ 0.1 (or $\Delta T_{CMB}/T_{CMB} \approx$ a few $\times 10^{-5}$; see Bennett et al. 2003b). Thus, when a single cluster field exhibits some broad central "bump," it is not necessarily the signature of an emission source; in fact, we shall demonstrate that *for our cluster sample as a whole*, the discrepancy between predicted and detected SZE profiles cannot be due to line-of-sight emissions. Likewise, the existence of a central trough may also be caused by primordial acoustic oscillations, rather than the SZE. The only way of
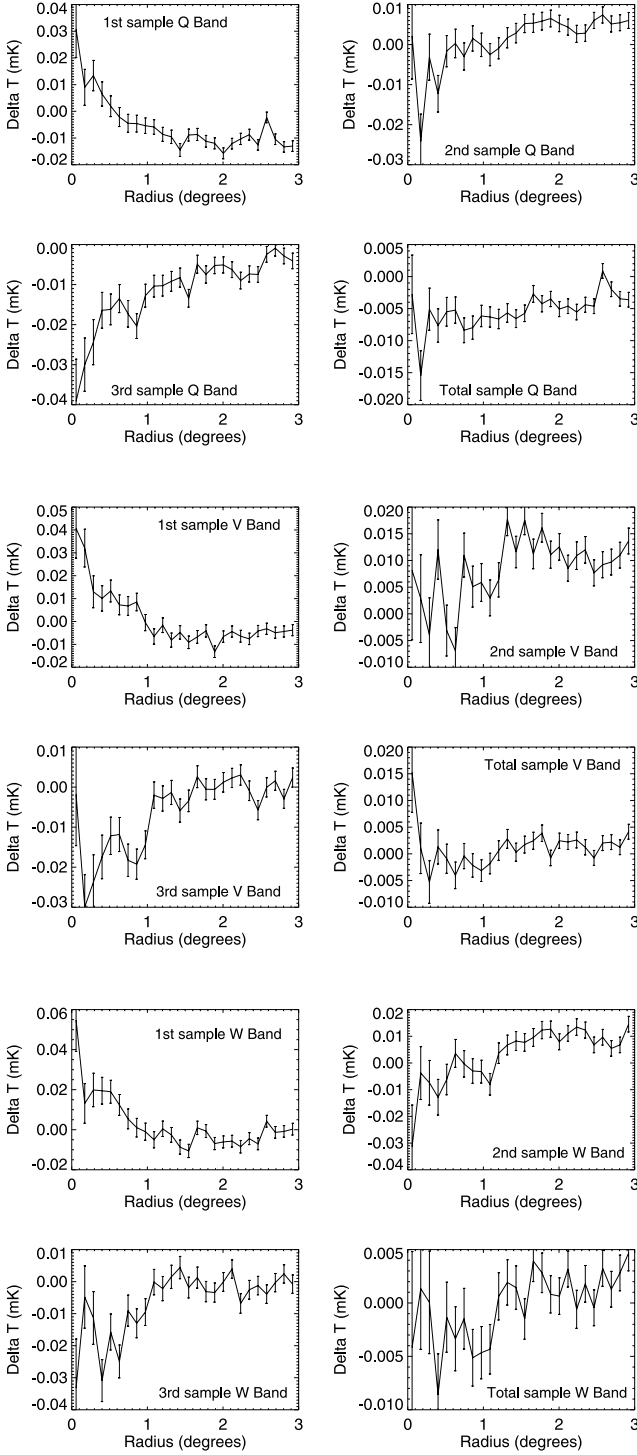

Fig. 8.—*WMAP* Q-, V-, and W- band radial profile (of CMB temperature deviation). For each band the first three graphs show the average profile of 33 fields, each centered at a randomly chosen position on the sky, while the last (*bottom right*) graph shows the average profile of 100 such fields; here the rms scatter of the data confirms the correctness of the size of the error bars.

knowing whether there is consistency between the *WMAP* data and cluster SZEs is to examine the *co-added* profiles of all the clusters, when the systematic effects that prevent one from determining the "continuum" level can largely be suppressed.

In order to be certain that the temperature does stabilize among co-added fields, we generated average radial profiles of 33 random

fields at a time (Fig. 8). If the primary acoustic peaks and troughs are stacked with arbitrary central alignment in this way, one would expect the fluctuation amplitude to be reduced from the ~ 0.1 mK value by a factor of $\approx \sqrt{30}$, to about 0.02 mK. This is completely borne out by our averaged random profiles, which also indicate that toward the larger ($2°-3°$) annuli, the CMB temperature deviations from the global mean value are very uniform, hovering close to zero. By the time 100 randomly generated profiles are averaged, the data points are smooth throughout all radii (Fig. 8). With the help of these plots (of the merged 100 fields), wherein the systematic variations are no longer a problem, we could verify whether the error bar on each radial bin (antenna random noise) is independent of other bins. The answer is yes, because the rms. scatter among the data points is found to be consistent with the size of the error bars.

Returning now to the averaging of 33 random fields (Fig. 8), the residual systematic excursions in the data are important for understanding the radial profile of the co-added cluster fields (Fig. 5). This is because both figures involve the stacking of a similar number of *WMAP* fields. Since the magnitude of any remaining systematic effect is, as can be seen in Figure 8, far less than the discrepancy between observed and expected SZE in our cluster sample, Figure 5, one must conclude that *the apparent incomplete SZE is not due to intrinsic sky variations in the CMB temperature recorded by WMAP*, i.e., it is a genuine anomaly that deserves an explanation.

5. INTERPRETATION

How can one reconcile a cosmological CMB origin with Figure 5? It is perhaps more reasonable to first examine whether, despite many generations of X-ray observatories measuring the X-ray properties of clusters, we are still misled by uncertainties on the hot ICM parameters. Then there is also the question of radio source contamination.

Could a steepening in the slope of the hot ICM density profile beyond the radius where the β model is well constrained by ROSAT data lead to an overestimation of the SZE? We pause to consider an extreme scenario under which the *WMAP*'s spatial resolution is so poor that the entire SZE of even a nearby cluster simply appears as a "point sink" at zero radius. If this is really the case, the *WMAP* radial profile of the SZE would have the shape of the PSF, with the flux within the entire profile being equal to the cluster SZE, integrated over all sight lines cutting through the cluster at various "impact parameters." For a β model, however, this total flux is dominated by the SZE at the outer radii, where the model is no longer well constrained by the X-ray data. The reason is that at any off-axis angle θ, the line-of-sight SZE has the form:

$$\Delta T_{\mathrm{SZ}}(\theta) = \Delta T_{\mathrm{SZ}}(0) \left[1 + (\theta/\theta_c)^2 \right]^{-(3\beta/2)+(1/2)}. \quad (4)$$

At least for our sample of clusters, *ROSAT* data fail to guide the model only at radii $\theta \gg \theta_c$, and typically at $\theta > 10'$ in real units.

The total X-ray–predicted SZE, integrated over all values of θ, is dominated by the values of $\Delta T_{\mathrm{SZ}}(\theta)$ in the range $\theta \gg \theta_c$, unfortunately. This is because

$$\Delta T_{\mathrm{SZ}}^{\mathrm{total}} = \int_0^\infty \Delta T_{\mathrm{SZ}}(\theta) \, 2\pi\theta \, d\theta, \quad (5)$$

and for $\theta \gg \theta_c$ the integral $\sim \theta^{-3(\beta-1)}$, which diverges at the upper integration limit, because the inequality $\beta < 1$ applies to

our clusters (see Table 1). In fact, from equation (3) it can also be seen that the total cluster mass, proportional to $\int n_e(r) \, r^2 dr$, scales with the upper cutoff radius in exactly the same way. Thus, the outcome of our analysis is that *if WMAP*'s spatial resolution is very poor, the X-ray model can overpredict the SZE by an arbitrarily large amount. This point was already raised in the recent papers of Benson et al. (2004) and Schmidt et al. (2005).

Specifically, while Schmidt et al. (2005) reported a steepening in the slope of the β model (i.e., less hot ICM) toward a cluster's outskirts by comparing *Chandra* and *ROSAT* data, Benson et al. (2004) found that, provided the SZE is evaluated over a radius commensurate with the resolution (or beam size) of the instrument, any difference among the predictions derived from the various sets of model parameters actually remains small.

In the context of this last point of Benson et al. (2004), we demonstrate that most of the results we obtained in the previous sections remain robust: the *WMAP* resolution is not as pessimistic as that depicted in the extreme scenario we just considered, because the detected SZE profiles are much wider than the instrument PSF. In fact, much of the SZE within the central $0°.5$ radius of "matching" with the *WMAP* beam is not due to the PSF leaking signals from large radii inwards. Instead, the opposite is true: there is a loss of inner signals outward, which only widens the actual gap between SZE prediction and observation. To test these statements, we choose a pair of β-model parameters typical to our cluster sample, viz. $\beta = 2/3$ and $\theta_c = 2'$, and truncate the full line-of-sight integrated SZE profile, equation (4), abruptly at $\theta = 10'$, resulting in the functional dependence

$$\Delta T_{\mathrm{SZ}}^{\mathrm{cutoff}}(\theta) =$$
$$\begin{cases} \Delta T_{\mathrm{SZ}}(0) \left[1 + 0.25(\theta/\mathrm{arcmin})^2 \right]^{-1/2}, & \theta \leq 10', \\ 0, & \text{otherwise.} \end{cases} \quad (6)$$

The reason for setting the cutoff at $10'$ is that for most of the clusters in our sample, Figure 1 indicates that the *ROSAT* data can constrain the surface brightness profile out to at least such a radius. If, after convolution of the truncated profile with the PSF, there is a significant reduction of the inner SZE, this would imply a severe flux overprediction problem at small radii by the *WMAP* PSF, which spreads signals inward from regions beyond $10'$, where the β model is no longer so reliable. Note that in our test we did not truncate the β model self-consistently by reducing the line-of-sight integration to reflect the projection effect of the cutoff at $\theta \leq 10'$. This is a separate question to be investigated below.

The outcome of the test is shown in Figure 9, where it can be seen that within $\theta \leq 0°.5$, the reduction in SZE by our truncation procedure is $\approx 12\%$ for the Q band, and much less for the V and W bands. This means that any incorrectness in the outer (questionable) parts of the β model, when coupled with the *WMAP* PSF spreading effect, cannot lead to an overprediction of the SZE within the central $0°.5$ radius by a factor of 4–6. Yet such factors are necessary to explain the average discrepancy between X-ray expectation and *WMAP*-observed SZE levels for the three cosmological filter passbands (see Fig. 5). We must also point out that in terms of PSF effects, the real problem is the opposite, viz. the loss of inner signals to the radii beyond, as borne out by the fact that when we convolved $\Delta T_{\mathrm{SZ}}^{\mathrm{cutoff}}(\theta)$ with the PSF and compared the total SZE over $\theta \leq 10'$ with the same quantity obtained before convolution, the ratio of the latter to the former ranges from 2.48 (Q band) through 5.31 (V band) to 5.61

FIG. 9.—Comparison between the SZE-predicted profile of two versions of the β-model, after each profile is convolved with the *WMAP* PSF (for the appropriate filter). Both versions use exactly the same model parameters as starting point, except one invokes the full model of eq. (4) with $\theta_c = 2'$ and $\beta = 2/3$ (*solid line*), while the other (*dashed line*) invokes a truncation of the model at $\theta = 10'$, i.e., eq. (6).

(W band). Since the average X-ray–predicted SZE profile is more centrally peaked than the *WMAP*-observed profile (Fig. 5), this means that the discrepancy between *ROSAT* and *WMAP* should have been even more pronounced if the original *intrinsic* profiles before PSF convolution were compared.

In order to assess the line-of-sight projection effect of the outer parts of the β model on the inner SZE prediction, we can divide the central decrement $\Delta T_{\mathrm{SZ}}(0)$ into two parts: contributions from
Fig. 10.—*XMM-Newton* deprojected best hot-ICM parameters of A2029. The plotted values are averaged over all three instruments, MOS1, MOS2, and PN. In the bottom graph, the solid line represents the β-model as fitted to the *ROSAT* data outside the "cooling flow" region, with the density profile then extrapolated inwards while assuming isothermality for all radii at the temperature given by Table 1 (i.e., ignoring the cooling core, which is exactly our procedure when we derived the predicted SZE flux from the parameters of Table 1). The reason for plotting the product of deprojected density and temperature is that the X-ray SZE prediction depends directly on this quantity. It can be seen that our method yields good agreement with *XMM-Newton* data, even though this cluster exhibits the worst discrepancy between X-ray and *WMAP* measurements.

the hot ICM within and beyond the truncation limit of $\theta = \theta_T = 10'$, respectively, i.e., we write

$$\Delta T_{\mathrm{SZ}}(0) \propto \int_0^{\theta_T} \left[1 + \left(\frac{\theta}{\theta_c} \right)^2 \right]^{-3\beta/2} d\theta$$
$$+ \int_{\theta_T}^{\infty} \left[1 + \left(\frac{\theta}{\theta_c} \right)^2 \right]^{-3\beta/2} d\theta. \qquad (7)$$

For our typical sample parameters of $\beta = 2/3$ and $\theta_c = 2'$, the ratio of the second term on the right side to the first term is 14.5%. It is clearly not of a magnitude large enough to explain the discrepancy of concern, which is at the 400%–600% level (Fig. 5). The same conclusion may be drawn about the other slightly off-axis sight lines of the innermost $0°.5$ radius.

The impact of uncertainties in the X-ray β model on the integrity of the present work may quantitatively be summarized in two points. First, we can calculate the significance of the average discrepancy between the predicted and observed SZE as depicted in Figure 5, taking into account (1) the random error bars shown in Figure 5 (i.e., antenna noise for each radial bin; see the end of § 3); (2) the systematic error per bin, which is also shown in Figure 5 and described in § 4; (3) the uncertainty in the β-model parameters manifested as errors in the model prediction for each bin, shown in Figure 5 as the vertical interval between the dashed and solid lines; and (4) systematic error in the β-model prediction for the inner radial bins due to unreliability of the model at the cluster outskirts coupled with the *WMAP* PSF smearing effect, as described in this section and quantified in Figure 9. When

all four error components are added in quadrature, we find that for the central $1'$ radius, the discrepancy between prediction and observation has the significance level of 2.73, 4.65, and 4.70 σ, respectively, for the Q, V, and W bands. This level becomes even higher if the next few bins are also included with our calculation.

On to our second summary point: as was argued earlier, since the total SZE (summed over all sight lines out to some limiting radius $\theta \gg \theta_c$) scales with θ as the total hot ICM mass (out to the same radius) does, we used Figure 5 to compute an ensemble average over our 31 member cluster sample for the ratio of the X-ray–predicted to *WMAP*-observed total SZE, out to $\theta = 10'$ (i.e., $\theta \gg \theta_c \approx 2'$). This ratio, which ranges from 1.49 (Q band) through 2.21 (V band) to 2.82 (W band), indicates by how much the X-ray β-model estimate of the hot ICM mass within the radius $\theta = 10'$ must be reduced in order to secure a match between *ROSAT* and *WMAP*. For the W band, which is the best (cleanest) cosmological filter of *WMAP*, the answer is close to 300%. It is somewhat surprising that the β-model can lead to such large errors in the X-ray gas mass: errors because of which many previous X-ray observations of the hot ICM have effectively been deemed meaningless. Note also that, as already explained, because the X-ray-predicted SZE profile is more centrally peaked than the *WMAP* profile, problems with the leakage of flux toward the $>10'$ radii by the *WMAP* PSF render the correct percentage reduction of the hot ICM mass even higher than 300%.

Could a "cooling flow" that exists in some clusters invalidate any estimate of central SZE, based on isothermal β-model fits to the ROSAT data? While remaining in the spirit of the foregoing discussion, viz. on the question of how the SZE predicted profile for the central $0°.5$ radius of "matching" with the *WMAP* beam

may be affected by the on-axis flux decrement, we turn to the possible role played by the cooling of cluster cores. By using the more accurate measurements of *Chandra*, Schmidt et al. (2005) found that a straightforward *ROSAT* β-model inference of $\Delta T_{SZ}(0)$ could lead to an overestimate of the quantity by less than a factor of 2. Apart from re-emphasizing that the *WMAP* observations are more discrepant from our X-ray predictions than by this factor, it must also be stressed that the *ROSAT* β models we employed are derived by fitting *only* the *ROSAT* data from regions lying beyond "cooling flow" radii. Thus, while it is true that the central cooling of the hot ICM causes $\Delta T_{SZ}(0)$ to decrease, any accompanying central peaking of the gas density that has not been taken into account by the β-model has the opposite effect. The net outcome depends on how the product $n_e(r)\,kT(r)$, i.e., the gas pressure, scales with radius *relative* to the β-model inferred without taking the "cooling flow" into account. After investigating our present sample, we found that "cooling flows" tend to *maintain or raise* the y_0 parameter, rather than lower it. We illustrate this point by showing in detail the situation of A2029, a cluster for which the discrepancy between *WMAP* and *ROSAT* is large (see Fig. 2). For this cluster, the product $n_e(r)\,kT(r)$ is constrained using the high-resolution data of *XMM-Newton*, and its deprojected radial profile as plotted in Figure 10 is shown to compare closely with the β model of Table 1 for A2029.

Could line-of-sight non-CMB emissions have contaminated the WMAP passbands? In the restricted venue of the center of the Coma cluster, Herbig et al. (1995) measured a SZE of $-270\ \mu$K when the prediction is $\approx -500\ \mu$K. The authors attributed the discrepancy to radio sources located along the central sight line, but not members of the cluster. If, *in general*, line-of-sight sources unrelated to the clusters are bright enough to affect the *WMAP* data, the phenomenon should also be present among noncluster directions, i.e., one should expect the same level of contamination to exist in the *WMAP* random fields. There is, however, no evidence for this, because the radial profiles of the $\sim$30 accumulated random fields reveal an average temperature deviation of ≈ 0.005 mK for the three cosmological bands of Q, V, and W (see Fig. 8), which is on par with the average asymptotic deviation among the co-added cluster fields. Moreover, such amounts are far less than the discrepancy between the predicted and observed SZE of Figure 5.

Could the clusters themselves be a significant source of emission in the WMAP passbands? There are two possibilities: diffuse emission from cosmic ray synchrotron radiation, and discrete radio sources. The former is in principle a possibility (e.g., Sarazin & Lieu 1998), and we are currently investigating it, but see the two paragraphs after next. Concerning the latter, one can get a good idea of the cluster radio-source occurrence probability by appealing to the Owens Valley radio interferometry survey (Bonamente et al. 2006), which finds, on average, approximately one radio source per cluster with $\sim$1 mJy brightness at 30 GHz. Since the Owens Valley sample is more distant than ours, with a mean separation of $\sim$1.5 Gpc, as opposed to $\sim$0.5 Gpc for our present sample, the brightness level should scale to 10 mJy, or 10^{-28} W m^{-2} Hz^{-1}. To reduce the SZE by invoking emission components, such components must account for an average CMB temperature increase of $\delta T_{CMB} \approx 5 \times 10^{-5}$ K distributed over the area of $0°.5$ angular radius.

Is the equivalent of one unresolved 10 mJy source within the same area sufficient? The conversion from δT_{CMB} to a change in the observed flux involves multiplying the Rayleigh-Jeans sky flux $2\pi k \delta T_{CMB}\nu^2/c^2$ by the solid angle factor $\delta\Omega/4\pi$, where $\delta\Omega = \pi\theta^2$ with $\theta = 0°.5$. This yields an excess flux at $\nu = 30$ GHz of 10^{-27} W m^{-2} Hz^{-1}, 10 times higher than the contribution

Fig. 11.—Radial profile of the filter ratio of the temperature discrepancy between SZE model and data, for the 31 co-added cluster fields of Fig. 5. The first plot gives V:Q ratio, the second is V:W, and the third is W:Q. If the missing flux responsible for the discrepancy has a blackbody spectrum, the filter ratios will equal unity.

from cluster radio sources. Such a conclusion is applicable to the Q band, which measures at a frequency only slightly higher than 30 GHz. For the W band, at a frequency of 94 GHz, the radio source contribution is at least 2 orders of magnitude short, because such sources typically have flux spectra $F_\nu \sim \nu^{-\alpha}$ where $\alpha \geq 2$.

Since any cluster emissions that may account for the less-than-expected SZE detection by *WMAP*, be they diffuse or discrete in
FIG. 12.—Cluster field-to-field CMB temperature variation as seen in the three *WMAP* passbands at each radial bin. The solid line represents the level expected from the combined effect of natural blank field (i.e., primary CMB) variation and the SZE contrasts among clusters. The dashed line represents the level expected if radio sources with average brightness comparable to the SZE decrement are present in each cluster, with no correlation between such sources and the properties of the hot ICM within the same cluster. The fact that both solid and dashed lines are above the level of the data fluctuations is evidence for the presence of neither the SZE, nor radio contaminations at the level that can offset the SZE.

form, are invariably nonthermal in nature, with a flux spectrum $F_\nu \sim \nu^{-2}$ or steeper, i.e., a very different spectral shape from the Rayleigh-Jeans $F_\nu \sim \nu^2$ dependence, another test would involve checking the *WMAP* band ratios of the SZE discrepancy. Thus, a cluster source is distinguished by its larger V- to W- band flux ratios, which even in the case of a power law as shallow as $F_\nu \sim \nu^{-0.5}$, is a factor of 3 more than the corresponding ratio for Rayleigh-Jeans spectra. Since the observed ratio of V:W for any extra radiation component that may account for the discrepancy in Figure 5 is close to the blackbody limit (see Fig. 11), we conclude that the resolution does not lie with discrete cluster radio sources.

In addition to the above, there is one more powerful test. If clusters do exhibit a normal SZE that is masked by self-emissions unrelated to the hot ICM, one would expect additional field-to-field variation of the CMB temperature at a given radial bin within our cluster sample, because the properties of the hot ICM and nonthermal radiation vary from cluster to cluster. At the very minimum, the rms fluctuation must equal that of the blank field and the differing degree of SZE from one hot ICM to the next, with the two effects added in quadrature. That even this minimum is already *less* than the observed rms within our cluster sample is depicted in Figure 12. In fact, the observed rms is at the same level as that of the blank fields, excluding not only nonthermal emissions, but also the SZE itself, unless one contrives a scenario in which the two are correlated with each other.

Could peculiarities in the hot ICM abundance or the gradual decline of the hot ICM temperature with radius be responsible? The general reasoning can always be applied, especially at the centers of clusters where physics are more complicated, to argue

that if there are bright and spectrally unresolved metallic lines, the density of the hot ICM electrons, which is ordinarily determined by assuming that over most the X-ray passband the emission is a continuum, may drop, resulting in a reduction of the expected SZE. In reality, however, the effect is very small. Thus, for example, in the case of A2029, the hot ICM abundance we originally used to calculate the SZE was 0.3 solar. Analysis of *XMM-Newton* data revealed the same abundance level (Fig. 10), hence, no change in the density of hot ICM electrons. As to the largescale radial temperature decline, numerical simulation of clusters (Romeo et al. 2005) indicates that the hot ICM temperature can be halved by the time one reaches the virial radius. Observationally, however, it is clear that at least out to the radius $R = 5r_c \sim 10'$, beyond which the hot ICM contribution of the SZE is negligible (see eq. [7]), there is no evidence for such a temperature drop. For instance, in the case of A2029, which has a core radius of $2'$, the hot ICM temperature as measured by *XMM-Newton* (Fig. 10) remains stable out to $10'$. Thus, the cooling of the hot ICM toward the cluster's outskirts is not the reason for the large discrepancy between *WMAP* and X-ray fluxes.

On the role of asphericity of either the central core or the entire cluster, and clumpiness of the hot ICM, these questions are harder to answer quantitatively. Given that we averaged over 31 clusters, however, any residual asphericity corrections must be very small, unless one contrives a scenario in which clusters have their major axes aligned along some preferred direction. Clumpiness is a phenomenon worthy of further research, because (to argue heuristically) while the X-ray observations measure $\langle n_e^2 \rangle$, the SZE probes $\langle n_e \rangle$. The two are trivially related to each

other if $\langle n_e \rangle^2 = \langle n_e^2 \rangle$, which occurs only when the gas is smooth. Once clumps are present, $\langle n_e^2 \rangle > \langle n_e \rangle^2$, so the X-ray prediction will overestimate the SZE flux. Although for the hot ICM beyond the central core it is difficult to envisage, from pressure balance considerations, how such high-temperature plasmas could exhibit a large degree of clumping, the situation may be different within the core itself, where the cooling of gas and other dynamic processes often occur. It would still be surprising if the factor of 6 discrepancy reported here for the W band could entirely be attributed to this effect. Nevertheless, in the absence of further observational evidence, or a sound physical argument, one should not exclude the scenario of hot ICM clumping as possible cause of our reported discrepancy.

Finally, one could ask *what if photon populations other than the CMB may exist to interact with the hot ICM electrons to "refill" the SZE flux?* Whether we are dealing with "upward" or "downward" scattering, the difficulty lies with the insufficient seed-photon flux at frequencies well below and above the *WMAP* passbands. This is the reason for the general belief that cluster SZE should cause a clean removal of the CMB from its original microwave passband of emission.

6. CONCLUSION

Formally, a statistically significant detection of the SZE across our entire cluster sample was achieved by *WMAP*. The level of this detection is very weak, however. Not only is the field-to-field variation of the CMB temperature within the sample (due to different clusters exerting unequal SZE on the CMB) nonexistent (Fig. 12), but the *measured* decrements of Figure 5 are consistent with nothing beyond the usual primary CMB anisotropy, viz. the systematic variations in the CMB average radial profile for a commensurate number of co-added blank (random) fields (Fig. 8). Of particular concern are the data of the W band, which is the passband containing the cleanest extragalactic signals (Bennett et al. 2003b). The statistical significance of an overall W-band SZE detection is $<3\ \sigma$, when the expected effect is far larger. Here we also note that a similar shallow decrement was seen in the Myers et al. (2004) paper, where the best-fit model had a ΔT_0 of 0.083 mK in the W band. This is much smaller than the predicted average decrement from our sample of 0.46 mK from

Table 1. Thus, taken at face value, one may even hold the opinion that there is in fact no strong evidence in the *WMAP* database for the SZE at all, *when the aggregate behavior of all the clusters in the sample*, rather than individual cases, is considered.

Naturally, the entire premise of this paper depends on the reliability of the original *WMAP* data. If there are any data-analysis issues with the *WMAP* processing that can explain the extra-diffuse emission seen in our SZE clusters, then our findings will be obsolete. However, this would severely implicate all the *WMAP* analysis done to date. One possible resolution is to look at the SZE, as probed using dedicated ground-based observatories. The SZE has already been detected in a large number of high-redshift clusters using interferometric techniques of higher resolution than the *WMAP* data (e.g., Carlstrom et al. 1996; Joy et al. 2001; Reese et al. 2002; Bonamente et al. 2006; LaRoque et al. 2005). Comparison of radio interferometry and X-ray data for the same clusters show that SZE-derived and X-ray derived masses and gas fractions are in agreement (Grego et al. 2001; LaRoque et al. 2005), and allows for a determination of the cosmic distance scale (Reese et al. 2002; Bonamente et al. 2006). There is not necessarily a conflict between our present results and the previous reported SZE detections for individual clusters. As can be seen from Figure 2, many of the clusters in our sample *do* exhibit the effect at approximately the anticipated level.

In summary, it is through the first detailed *radial profile* comparison between X-ray and microwave observations that an apparent sample-wide discrepancy between the expected and measured levels of SZE from some of the best known clusters of galaxies was uncovered. The difficulty lies with the average behavior of our randomly selected cluster sample, which could still be suffering from systematic, yet hitherto unknown, biases. Nonetheless, the average CMB temperature decrement is sufficiently shallow to be interpreted simply as the usual primary CMB anisotropy: there is no need to invoke any SZE at this stage of the *WMAP* analysis.
